

## Text Clustering

1

## Clustering

- Partition unlabeled examples into disjoint subsets of *clusters*, such that:
  - Examples within a cluster are very similar
  - Examples in different clusters are very different
- Discover new categories in an *unsupervised* manner (no sample category labels provided).

2

## Clustering Example

3

## Hierarchical Clustering

- Build a tree-based hierarchical taxonomy (*dendrogram*) from a set of unlabeled examples.

- Recursive application of a standard clustering algorithm can produce a hierarchical clustering.

4

## Agglomerative vs. Divisive Clustering

- *Agglomerative* (*bottom-up*) methods start with each example in its own cluster and iteratively combine them to form larger and larger clusters.
- *Divisive* (*partitional, top-down*) separate all examples immediately into clusters.

5

## Direct Clustering Method

- *Direct clustering* methods require a specification of the number of clusters,  $k$ , desired.
- A *clustering evaluation function* assigns a real-value quality measure to a clustering.
- The number of clusters can be determined automatically by explicitly generating clusterings for multiple values of  $k$  and choosing the best result according to a clustering evaluation function.

6

## Hierarchical Agglomerative Clustering (HAC)

- Assumes a *similarity function* for determining the similarity of two instances.
- Starts with all instances in a separate cluster and then repeatedly joins the two clusters that are most similar until there is only one cluster.
- The history of merging forms a binary tree or hierarchy.

7

## HAC Algorithm

Start with all instances in their own cluster.

Until there is only one cluster:

Among the current clusters, determine the two clusters,  $c_i$  and  $c_j$ , that are most similar.

Replace  $c_i$  and  $c_j$  with a single cluster  $c_i \cup c_j$

8

## Cluster Similarity

- Assume a similarity function that determines the similarity of two instances:  $sim(x, y)$ .
  - Cosine similarity of document vectors.
- How to compute similarity of two clusters each possibly containing multiple instances?
  - Single Link**: Similarity of two most similar members.
  - Complete Link**: Similarity of two least similar members.
  - Group Average**: Average similarity between members.

9

## Single Link Agglomerative Clustering

- Use maximum similarity of pairs:
 
$$sim(c_i, c_j) = \max_{x \in c_i, y \in c_j} sim(x, y)$$
- Can result in “straggly” (long and thin) clusters due to *chaining effect*.
  - Appropriate in some domains, such as clustering islands.

10

## Single Link Example

11

## Complete Link Agglomerative Clustering

- Use minimum similarity of pairs:
 
$$sim(c_i, c_j) = \min_{x \in c_i, y \in c_j} sim(x, y)$$
- Makes more “tight,” spherical clusters that are typically preferable.

12

## Complete Link Example

13

## Computational Complexity

- In the first iteration, all HAC methods need to compute similarity of all pairs of  $n$  individual instances which is  $O(n^2)$ .
- In each of the subsequent  $n-2$  merging iterations, it must compute the distance between the most recently created cluster and all other existing clusters.
- In order to maintain an overall  $O(n^2)$  performance, computing similarity to each other cluster must be done in constant time.

14

## Computing Cluster Similarity

- After merging  $c_i$  and  $c_j$ , the similarity of the resulting cluster to any other cluster,  $c_k$ , can be computed by:
  - Single Link:
 
$$\text{sim}((c_i \cup c_j), c_k) = \max(\text{sim}(c_i, c_k), \text{sim}(c_j, c_k))$$
  - Complete Link:
 
$$\text{sim}((c_i \cup c_j), c_k) = \min(\text{sim}(c_i, c_k), \text{sim}(c_j, c_k))$$

15

## Group Average Agglomerative Clustering

- Use average similarity across all pairs within the merged cluster to measure the similarity of two clusters.
 
$$\text{sim}(c_i, c_j) = \frac{1}{|c_i \cup c_j|(|c_i \cup c_j| - 1)} \sum_{\vec{x} \in (c_i \cup c_j)} \sum_{\vec{y} \in (c_i \cup c_j), \vec{y} \neq \vec{x}} \text{sim}(\vec{x}, \vec{y})$$
- Compromise between single and complete link.
- Averaged across all ordered pairs in the merged cluster instead of unordered pairs *between* the two clusters.

16

## Computing Group Average Similarity

- Assume cosine similarity and normalized vectors with unit length.
- Always maintain sum of vectors in each cluster.
 
$$\vec{s}(c_j) = \sum_{\vec{x} \in c_j} \vec{x}$$
- Compute similarity of clusters in constant time:
 
$$\text{sim}(c_i, c_j) = \frac{(\vec{s}(c_i) + \vec{s}(c_j)) \bullet (\vec{s}(c_i) + \vec{s}(c_j)) - (|c_i| + |c_j|)}{(|c_i| + |c_j|)(|c_i| + |c_j| - 1)}$$

17

## Non-Hierarchical Clustering

- Typically must provide the number of desired clusters,  $k$ .
- Randomly choose  $k$  instances as *seeds*, one per cluster.
- Form initial clusters based on these seeds.
- Iterate, repeatedly reallocating instances to different clusters to improve the overall clustering.
- Stop when clustering converges or after a fixed number of iterations.

18

## K-Means

- Assumes instances are real-valued vectors.
- Clusters based on *centroids*, *center of gravity*, or mean of points in a cluster,  $c$ :

$$\bar{\mu}(c) = \frac{1}{|c|} \sum_{\vec{x} \in c} \vec{x}$$

- Reassignment of instances to clusters is based on distance to the current cluster centroids.

19

## Distance Metrics

- Euclidian distance ( $L_2$  norm):

$$L_2(\vec{x}, \vec{y}) = \sum_{i=1}^m (x_i - y_i)^2$$

- $L_1$  norm:

$$L_1(\vec{x}, \vec{y}) = \sum_{i=1}^m |x_i - y_i|$$

- Cosine Similarity (transform to a distance by subtracting from 1):

$$1 - \frac{\vec{x} \cdot \vec{y}}{|\vec{x}| \cdot |\vec{y}|}$$

20

## K-Means Algorithm

Let  $d$  be the distance measure between instances.

Select  $k$  random instances  $\{s_1, s_2, \dots, s_k\}$  as seeds.

Until clustering converges or other stopping criterion:

For each instance  $x_i$ :

Assign  $x_i$  to the cluster  $c_j$  such that  $d(x_i, s_j)$  is minimal.

(Update the seeds to the centroid of each cluster)

For each cluster  $c_j$

$$s_j = \mu(c_j)$$

21

## K Means Example (K=2)

22

## Time Complexity

- Assume computing distance between two instances is  $O(m)$  where  $m$  is the dimensionality of the vectors.
- Reassigning clusters:  $O(kn)$  distance computations, or  $O(knm)$ .
- Computing centroids: Each instance vector gets added once to some centroid:  $O(nm)$ .
- Assume these two steps are each done once for  $I$  iterations:  $O(Iknm)$ .
- Linear in all relevant factors, assuming a fixed number of iterations, more efficient than  $O(n^2)$  HAC.

23

## Seed Choice

- Results can vary based on random seed selection.
- Some seeds can result in poor convergence rate, or convergence to sub-optimal clusterings.
- Select good seeds using a heuristic or the results of another method.

24

## Buckshot Algorithm

- Combines HAC and K-Means clustering.
- First randomly take a sample of instances of size  $\sqrt{n}$
- Run group-average HAC on this sample, which takes only  $O(n)$  time.
- Use the results of HAC as initial seeds for K-means.
- Overall algorithm is  $O(n)$  and avoids problems of bad seed selection.

25

## Text Clustering

- HAC and K-Means have been applied to text in a straightforward way.
- Typically use **normalized**, TF/IDF-weighted vectors and cosine similarity.
- Optimize computations for sparse vectors.
- Applications:
  - During retrieval, add other documents in the same cluster as the initial retrieved documents to improve recall.
  - Clustering of results of retrieval to present more organized results to the user (à la Northernlight folders).
  - Automated production of hierarchical taxonomies of documents for browsing purposes (à la Yahoo & DMOZ).

26

## Soft Clustering

- Clustering typically assumes that each instance is given a “hard” assignment to exactly one cluster.
- Does not allow uncertainty in class membership or for an instance to belong to more than one cluster.
- **Soft clustering** gives probabilities that an instance belongs to each of a set of clusters.
- Each instance is assigned a probability distribution across a set of discovered categories (probabilities of all categories must sum to 1).

27

## Expectation Maximization (EM)

- Probabilistic method for soft clustering.
- Direct method that assumes  $k$  clusters:  $\{c_1, c_2, \dots, c_k\}$
- Soft version of  $k$ -means.
- Assumes a probabilistic model of categories that allows computing  $P(c_i | E)$  for each category,  $c_i$ , for a given example,  $E$ .
- For text, typically assume a naïve-Bayes category model.
  - Parameters  $\theta = \{P(c_j), P(w_j | c_j) : i \in \{1, \dots, k\}, j \in \{1, \dots, |V|\}\}$

28

## EM Algorithm

- Iterative method for learning probabilistic categorization model from unsupervised data.
- Initially assume random assignment of examples to categories.
- Learn an initial probabilistic model by estimating model parameters  $\theta$  from this randomly labeled data.
- Iterate following two steps until convergence:
  - **Expectation (E-step)**: Compute  $P(c_i | E)$  for each example given the current model, and probabilistically re-label the examples based on these posterior probability estimates.
  - **Maximization (M-step)**: Re-estimate the model parameters,  $\theta$ , from the probabilistically re-labeled data.

29

## Learning from Probabilistically Labeled Data

- Instead of training data labeled with “hard” category labels, training data is labeled with “soft” probabilistic category labels.
- When estimating model parameters  $\theta$  from training data, weight counts by the corresponding probability of the given category label.
- For example, if  $P(c_1 | E) = 0.8$  and  $P(c_2 | E) = 0.2$ , each word  $w_j$  in  $E$  contributes only 0.8 towards the counts  $n_1$  and  $n_{1j}$ , and 0.2 towards the counts  $n_2$  and  $n_{2j}$ .

30

## Naïve Bayes EM

Randomly assign examples probabilistic category labels.  
Use standard naïve-Bayes training to learn a probabilistic model with parameters  $\theta$  from the labeled data.  
Until convergence or until maximum number of iterations reached:  
**E-Step:** Use the naïve Bayes model  $\theta$  to compute  $P(c_i | E)$  for each category and example, and re-label each example using these probability values as soft category labels.  
**M-Step:** Use standard naïve-Bayes training to re-estimate the parameters  $\theta$  using these new probabilistic category labels.

31

## Semi-Supervised Learning

- For supervised categorization, generating labeled training data is expensive.
- **Idea:** Use unlabeled data to aid supervised categorization.
- Use EM in a *semi-supervised* mode by training EM on both labeled and unlabeled data.
  - Train initial probabilistic model on user-labeled subset of data instead of randomly labeled unsupervised data.
  - Labels of user-labeled examples are “frozen” and never relabeled during EM iterations.
  - Labels of unsupervised data are constantly probabilistically relabeled by EM.

32

## Semi-Supervised Example

- Assume “quantum” is present in several labeled physics documents, but “Heisenberg” occurs in *none* of the *labeled* data.
- From labeled data, learn that “quantum” is indicative of a physics document.
- When labeling unsupervised data, label several documents with “quantum” *and* “Heisenberg” correctly with the “physics” category.
- When retraining, learn that “Heisenberg” is also indicative of a physics document.
- Final learned model is able to correctly assign documents containing *only* “Heisenberg” to physics.

33

## Semi-Supervision Results

- Experiments on assigning messages from 20 Usenet newsgroups their proper newsgroup label.
- With very few labeled examples (2 examples per class), semi-supervised EM improved accuracy from 27% (supervised data only) to 43% (supervised + unsupervised data).
- With more labeled examples, semi-supervision can actually decrease accuracy, but refinements to standard EM can prevent this.
- For semi-supervised EM to work, the “natural clustering of data” must be consistent with the desired categories.

34
